ABSTRACT. Experiments with plasmas having nearly equal concentrations of deuterium and tritium have been carried out on TFTR. To date (September 1995), the maximum fusion power has been 10.7 MW, using 39.5 MW of neutral beam heating, in a supershot discharge and 6.7 MW in a high β_p discharge following a current ramp-down. The fusion power density in the core of the plasma has reached 2.8 MW/m³, exceeding that expected in the International Thermonuclear Experimental Reactor (ITER). The energy confinement time τ_E is observed to increase in DT, relative to D plasmas, by 20% and the $n_i(0) \cdot T_i(0) \cdot \tau_E$ product by 55%. The improvement in thermal confinement is caused primarily by a decrease in ion heat conductivity in both supershot and limiter H mode discharges. Extensive lithium pellet injection increased the confinement time to 0.27 s and enabled higher current operation in both supershot and high β_p discharges. First measurements of the confined alpha particles have been performed and found to be in good agreement with TRANSP simulations

assuming classical confinement. Measurements of the alpha ash profile have been compared with simulations using particle transport coefficients from helium gas puffing experiments. The loss of energetic alpha particles to a detector at the bottom of the vessel is well described by the first-orbit loss mechanism. No loss due to alpha particle driven instabilities has yet been observed. ICRF heating of a DT plasma, using the second harmonic of tritium, has been demonstrated. DT experiments on TFTR will continue both to explore the physics underlying the ITER design and to examine some of the physics issues associated with an advanced tokamak reactor.

1. MAXIMIZING THE FUSION REACTIVITY IN TFTR

Since December 1993, the Tokamak Fusion Test Reactor (TFTR) has been operated routinely with plasmas containing high concentrations of tritium. A variety of experiments has been conducted to study the effects of tritium on the plasma confinement and heating and the physics of the alpha particles produced by deuterium-tritium (DT) fusion. These TFTR experiments, which follow the JET Preliminary Tritium Experiment (PTE) in 1991 [1] with low concentrations ($\sim 10\%$) of tritium, are the first to achieve nearly optimal DT mixtures and high fusion power densities in magnetically confined plasmas. As in the JET-PTE, injection of high power tritium and deuterium neutral beams (NBI) has proved very successful [2–6] for producing high DT fusion power in TFTR. The TFTR NBI sources inject almost tangentially; six of the sources inject co-parallel and six counter-parallel to the plasma current. The capability to switch each neutral beam source from deuterium to tritium operation and back on successive plasma shots has minimized the tritium consumption and has enabled careful comparisons to be made between similar D-only and DT plasmas. The total NBI power has reached 39.5 MW in DT using 7 T and 5 D sources (the NBI sources produce about 10% more injected power when operating in tritium). The NBI pulse has been typically 0.7–2.0 s in duration. At 5 September 1995, a total of 2.34 g (22.5 kCi) of tritium had been introduced into the vacuum vessel by NBI and gas puffing. At that time, the total inventory of tritium in the vacuum vessel and neutral beam vacuum system following regeneration of the pumping cryo-panels (measured total tritium input minus tritium exhaust) was 0.82 g (7.9 kCi).

The highest fusion rates in TFTR for both DT and D-only plasmas have been obtained in ‘supershots’ [7], characterized by very high central ion temperatures, $T_i(0) = 20\text{--}40\text{ keV} \gg T_e(0) = 10\text{--}12\text{ keV}$, highly peaked profiles of the density and ion temperature, a broad electron temperature profile and enhanced energy confinement. Supershots in TFTR are produced with NBI heating when the edge influxes of hydrogenic species and carbon are reduced so that the plasma core is fuelled

predominantly by the injected neutrals. In addition to the enhanced confinement, this provides the advantage for DT experiments that the central ion species mix can be varied by changing the fraction of sources injecting tritium. The edge influxes of hydrogenic species and carbon have been further reduced through the injection of solid lithium pellets (1–4 pellets each containing typically 4×10^{20} atoms) into the ohmic phase of the discharge, 1.5–0.5 s prior to NBI [8]. The lithium rapidly leaves the plasma and is not a significant source of plasma dilution during NBI. The use of lithium conditioning has increased the plasma current at which the supershot characteristics are obtained [9] and increased the highest energy confinement time to 0.33 s in a 2.3 MA plasma with 17 MW of tritium NBI; this confinement time is approximately 2.4 times the prediction of ITER-89P scaling [10], based on an average ion mass of 2.7. The DT experiments have been conducted in plasmas with major radius of 2.45–2.62 m and minor radius of 0.80–0.97 m, having a nominally circular plasma cross-section with a toroidal carbon limiter on the inboard side. The toroidal magnetic field and plasma current have been in the ranges 4.6–5.5 T and 0.6–2.7 MA respectively.

In both DT and D-only supershots, there is a strong dependence of the peak fusion rate on the total plasma energy, namely $S_{DT} \propto W_{tot}^{1.9}$ [5, 11]. The β limit in supershots has been found to scale similarly to the Troyon limit [12, 13], so that, for fixed plasma size, $W_{tot,max} \propto I_p B_T$, where I_p is the plasma current and B_T the toroidal field. A major effort has been undertaken in the past year to increase the maximum toroidal field (TF) in TFTR to exploit the improved confinement of supershots at the full NBI power available in DT operation. After extensive analysis and review of the TF coil structure and rearrangement of the power supplies, it has proved possible to increase the TF coil current by 16% although, to date, an 8% increase has been used in plasma experiments. Coupled with a corresponding increase in the plasma current, this has increased the maximum sustainable energy in supershots by about 16%, which projects to an increase of about 30% in the possible DT fusion power.

Figure 1 shows the time evolution of the DT fusion power and plasma stored energy for four plasmas from

FIG. 1. Evolution of the NBI power, plasma stored energy and fusion power for the four discharges producing the highest powers. For the three non-disruptive shots, the major radius was 2.52 m, minor radius 0.87 m, toroidal magnetic field 5.5 T and plasma current 2.7 MA. For the shot which disrupted, the toroidal magnetic field was 5.1 T and the plasma current 2.5 MA.

the experiments in May 1994 and October 1994 leading up to the shot producing the highest instantaneous power of 10.7 ± 0.8 MW. The fusion power is measured by detectors for the 14 MeV neutrons [14] while the plasma energy is determined from magnetic data and includes the energy in the unthermalized injected deuterons and tritons. In the experiment in May, the final shot disrupted after 0.44 s of NBI when it reached the β limit at a Troyon normalized β , $\beta_N (= 10^8 \times 2\mu_0 \langle p \rangle a / B_T I_p$, where $\langle p \rangle$ is the volume average pressure and a is the plasma minor radius) of 1.9. At the higher toroidal field and plasma current available in October, TFTR was able to produce the same fusion power in a stable discharge. The shot producing the highest fusion power did suffer a minor disruption after 0.47 s of heating when β_N reached 1.8. It should be noted that because the pressure profiles in supershots are highly peaked, the parameter of relevance for fusion performance, $\beta_N^* (= 10^8 \cdot 2\mu_0 \sqrt{\langle p^2 \rangle} a / B_T I_p$, where $\sqrt{\langle p^2 \rangle}$ is the root mean square plasma pressure) reached 2.8 in this plasma. In DT shots with the current profile modified by ramping down the current, a fusion power of 6.7 MW has been achieved at $\beta_N = 3.0$ and $\beta_N^* = 4.2$ [15].

Figure 2 shows the peak fusion power, averaged over a 40 ms interval, as a function of total heating power (NBI plus ohmic power; the latter is, however, negligible for $P_{\text{tot}} > 10$ MW) for supershots with NBI heating only and with more than 2 MW tritium NBI. Plasmas with a nearly optimal DT mixture and those with extensive lithium pellet conditioning are distinguished. A non-linear dependence of the DT fusion power on the heating power is apparent in these data. The highest ratio Q of the fusion power to the total heating power, $Q \approx 0.27$, was obtained on four shots. The shot producing 5.6 MW with only 21 MW NBI was conditioned with four lithium pellets and achieved a total energy confinement time of 0.27 s. The thermal plasma (electrons plus thermalized ions) accounted for about 65% of the total energy in this plasma.

The time evolution of the fusion reactivity in TFTR has been analysed with the TRANSP code [16, 17]. The deposition, orbit loss and slowing down of the injected T and D neutrals are calculated using the measured profiles of the electron density and the electron and ion temperatures. For the subset of DT plasmas in Fig. 2 analysed in detail by TRANSP, the model generally matches the total plasma energy within 10% and the total DT neutron rate within 25%. A further validation of the model is provided by comparing the calculated profile of the DT neutron emission with measurements from 10 collimated neutron detectors. In TFTR, the edge recycling is dominated by

FIG. 2. Dependence of the peak DT fusion power output on the total heating power. The data are for supershots with at least one NBI source injecting pure tritium. Shots with nearly optimal tritium fraction, $0.4 < P_{T-NBI}/P_{NBI} < 0.8$, and shots with two or more lithium pellets before NBI are distinguished.

deuterium since the total exposure of the limiter to tritium is small [18]. Modelling of plasmas with varying fractions of D and T injection has demonstrated that, despite the reduced level of recycling necessary for supershots, the fuelling of the core of supershots by the edge influx is quite significant [17].

In the TRANSP code, the injected deuterons and tritons are modelled as slowing classically, without radial transport, until they reach the average thermal ion energy, which can reach half of the average injection energy in good supershots. The total fusion reactivity is then the sum of components arising from thermal ions, and from reactions of the unthermalized ions with the thermal ions (beam-target reactions) and each other (beam-beam reactions). In the plasmas producing the highest fusion power, the thermonuclear component dominates the DT reaction rate in the dense core ($r/a \leq 0.25$), although the beam-target component typically accounts for $\sim 50\%$ and the beam-beam component for $\sim 20\%$ of the overall fusion rate. However, for these plasmas, the decomposition of the reaction rate into these three calculational components can be somewhat misleading, for two reasons. On the one hand, almost all of the tritium comes originally from the NBI, which is essential for fuelling as well as heating. On the other, in the hot plasma core, the non-Maxwellian ion distribution does *not* in fact increase the DT reactivity compared to that of a plasma having a locally thermalized ion distribution with the same total fuel energy and particle densities. It is the hot ion ($T_i > T_e$) nature of these plasmas, rather than the non-Maxwellian ion distribution, that enhances the DT reactivity compared to that of an isothermal ($T_e = T_i$) plasma with the same total energy and particle densities.

The plasma with exceptional confinement produced by lithium conditioning which achieved a global Q of 0.27 (Fig. 2) is calculated to have reached a central Q , defined as the ratio of the local fusion power to the heating power density, of 0.75. The central fusion power densities achieved in the high performance TFTR supershots, 1.5–2.8 MW/m³, are comparable to or greater than those expected in ITER [19] at a total fusion power of 1500 MW.

2. CONFINEMENT OF FUSION ALPHA PARTICLES

The losses of energetic fusion alpha particles from DT plasmas have been measured by four energy and pitch angle resolving particle detectors mounted near the vacuum vessel wall at 20, 45, 60 and 90° below the outboard midplane, i.e. in the direction of the ion ∇B drift.

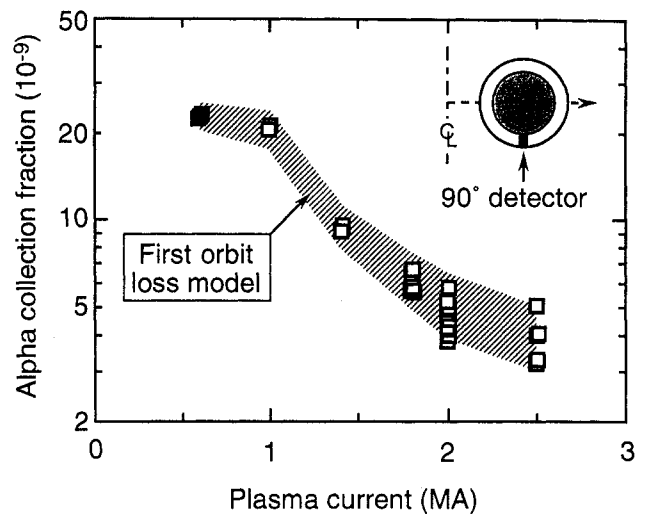

FIG. 3. Dependence of the loss rate of energetic alpha particles on the plasma current. The location of the detector is indicated in the inset. The shaded region shows the loss rate calculated for first orbit losses. The data were normalized to the calculation at 0.6 MA (solid points) where all trapped alpha particles are lost.

Scans of the plasma current have shown that in MHD quiescent plasmas, the alpha loss rate and pitch angle distribution at the 90° detector scale as expected for the prompt loss of particles born on unconfined orbits. This is shown in Fig. 3. However, for the detectors nearer the midplane, the first-orbit loss model does not adequately fit the data. Collisional and stochastic orbit losses in the toroidal field ripple are being investigated to explain these data.

Bursts of alpha particle loss are sometimes correlated with MHD activity in the plasma. In general, the losses are similar to those previously reported for energetic fusion products in D-only plasmas [20] and represent only a small fraction of the alpha population. However, at major disruptions, losses of energetic alpha particles estimated to be up to 10% of the alpha population have been observed to occur in ~ 2 ms during the thermal quench phase while the total current is still unperturbed. Such losses, which are observed mainly on the 90° detector, could have a serious impact on first-wall components in a reactor.

The energy distribution of the alpha particles confined in the plasma has been measured for the first time in TFTR [21]. Alphas in the range 0.5–3.5 MeV have been detected through conversion to neutral helium by double charge exchange in the high density neutral cloud surrounding an ablating lithium pellet. The pellet was injected after the end of NBI, to improve its penetration,

FIG. 4. Alpha particle energy distribution at the centre of a DT plasma 0.2 s after the end of the NBI. The measurements are normalized to the TRANSP calculation at the solid point.

but before the alpha population had decayed. The measured spectrum is compared with the TRANSP calculation in Fig. 4. The alpha population in the lower energy range 0.1–0.6 MeV has been detected by absolutely calibrated spectrometry of charge exchange recombination emission [22]. The intensities of the detected signals are within a factor 2 of calculations by TRANSP.

The radial profiles of thermalized alpha particles, the helium ash, have been measured by comparing charge exchange recombination line emission from helium in otherwise similar DT and D-only plasmas [23]. The initial measurements have been found to be consistent with TRANSP modelling for the helium profile based on transport coefficients that had been previously determined by using external helium gas puffs [24]. With these same transport coefficients, helium ash accumulation would not quench ignition in ITER provided the density of helium at the plasma edge can be controlled.

Previous experiments in TFTR [25] and DIII-D [26] had shown that the toroidal Alfvén eigenmode (TAE), which could be driven in a reactor by the population of energetic alpha particles, could be destabilized by the energetic ion populations created either by NBI or ICRF heating. The initial DT experiments in TFTR, however, showed no signs of instability in the TAE frequency range and the alpha particle loss rate remained a constant fraction of the alpha production rate as the alpha pressure increased, suggesting that deleterious collective alpha instabilities were not being excited. Theory [27, 28] has since shown that although TFTR achieves levels of the

alpha particle driving terms comparable to those of a reactor, the damping of the mode in supershot conditions is generally stronger than the alpha particle drive.

3. CONFINEMENT IN DT PLASMAS

In the first DT experiments in TFTR, it was immediately apparent that the overall energy confinement in supershots is significantly better in DT plasmas than in comparable D-only plasmas. The central ion and electron temperatures also increased in the DT plasmas. Differences in the fast ion thermalization are expected for tritium NBI and the fusion alpha particles can provide additional heating. The effect of a possible scaling of confinement with isotopic mass has been maximized and the alpha particle heating minimized by comparing supershots with D-only and T-only NBI.

Analysis has shown that the improvement in confinement appears to be primarily in the ion channel [29, 30].

FIG. 5. Variation of (a) the global energy confinement time and (b) the inferred total ion thermal diffusivity at the half minor radius with the average ion mass. Data are for supershots with varying fractions of deuterium and tritium NBI.

Figure 5 shows the variation of the global energy confinement time and the ion thermal diffusivity at the half minor radius for a set of plasmas with similar heating powers, currents and plasma geometry and varying fractions of tritium NBI. In the highest performance supershots produced so far, the alpha particle heating of the electrons amounts to only about 1 MW out of a total of about 10 MW, making its detection difficult. The electron temperature has been modelled in TRANSP for a quiescent DT plasma using the electron thermal diffusivity for a D-only reference shot. This modelling showed that if the alpha particle heating were entirely classical, it would produce about half of the measured increase in the central electron temperature. The electron temperature rise is consistent with the combination of alpha particle heating and scaling of the confinement with isotopic mass.

Supershots with H mode characteristics have been studied in both DT and D-only plasmas [31, 32]. The DT H mode plasmas have exhibited transient confinement times up to 0.24 s, which represents an enhancement by a factor of 4 relative to the ITER-89P scaling [10] while corresponding D plasmas had enhancements of ~ 3.2 . Across the transition to the H mode, the ion heat conductivity in the outer region of the plasma ($r/a > 0.4$) decreased by a factor of 2–3 in the DT plasmas whereas in D plasmas the reduction factor was much lower (< 1.5) [32]. The edge localized modes (ELMs), however, were much larger during the DT H modes. This suggests that ITER DT plasmas may be more susceptible to giant ELMs than inferred from D-only experiments. The power threshold for the transition to an H mode was similar in the discharges with D-only and DT NBI. However, although the tritium content in the core of the DT plasmas at the time of the H mode transition was determined, from collimated neutron measurements, to be as high as 75%, it was much lower in the scrape-off layer, of order 1%, as determined by measurements of the H_α , D_α , T_α line emission [18] because the recycling influx is still predominantly deuterium from earlier exposure of the carbon limiter surface. The plasma composition at the outer boundary at the time of the H mode transition remains uncertain.

4. HEATING BY ICRF WAVES IN DT PLASMAS

The interactions of waves in the ion cyclotron range of frequencies (ICRF) have also been investigated in DT plasmas [33–35]. The ICRF antennas have operated well during DT experiments and the increased radiation field,

from both the DT neutrons and the tritium β decay, has not affected their performance.

The initial experiments combining ICRF and neutral beam heating in DT plasmas focused on the physics of ICRF waves. This is complicated by the possibility of multiple, spatially separated ion resonances and by potential damping on the alpha particles. In TFTR supershots positioned for good coupling of the ICRF power and with the second harmonic tritium heating layer coincident with the Shafranov shifted axis at $R \approx 2.82$ m, the degenerate second harmonic deuterium and fundamental hydrogen resonance layer is out of the plasma on the low field side, but the fundamental deuterium heating layer is in the plasma on the high field side at $R \approx 2.1$ m. Second harmonic tritium heating at a power of 5.5 MW has resulted in an increase of the central ion temperature from 26 to 36 keV in a plasma with 23.5 MW of neutral beam heating (60% in tritium NBI). The electron temperature increased from 8.5 to 10.5 keV owing to both direct

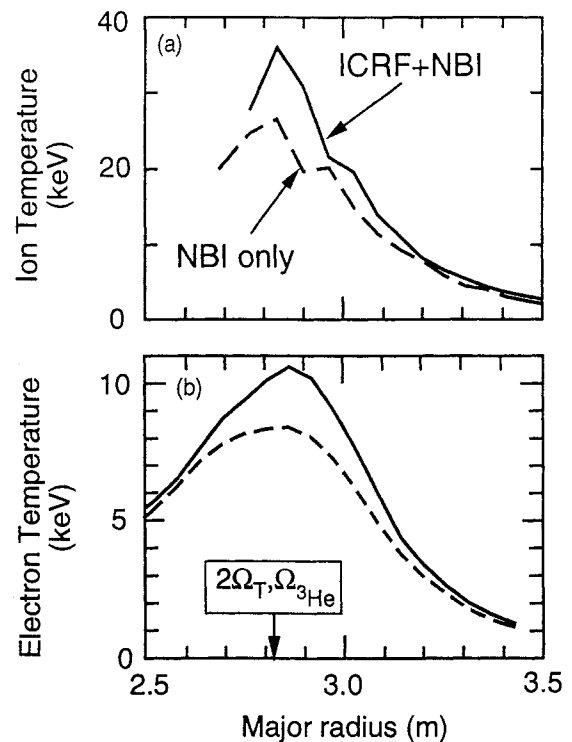

FIG. 6. Profiles of (a) the ion and (b) the electron temperature for supershot plasmas heated by 13.5 MW tritium and 10.0 MW deuterium NBI, with and without 5.5 MW of ICRF heating. To increase the single pass ICRF absorption, 2% ^3He was added. The conditions were chosen to place the degenerate second harmonic tritium, fundamental ^3He resonance layer on-axis. In addition to the increase in temperature, the DT reaction rate increased by about 10% with the ICRF heating.

electron damping and minority tail heating from a 2% ^3He minority which was added to increase the single pass wave damping. These results are shown in Fig. 6. Similar heating was also measured in discharges in which no ^3He was added. In separate experiments in which the ICRF power was modulated to increase the measurement sensitivity, the ion heating was found to be a maximum when the second harmonic tritium layer was on-axis. These results indicate that ICRF waves can be used to heat a DT plasma with core second harmonic tritium damping. The measured second harmonic tritium damping is consistent with calculations by the 2-D ICRF code (SPRUCE) incorporated in TRANSP [34].

Majeski et al. [36] have suggested that an ion Bernstein wave (IBW) excited by mode conversion from a fast wave at the $n_{\parallel}^2 = S$ layer in a multiple ion species plasma, such as DT, could be used for electron heating or to drive localized electron currents. Experiments using mixed ^3He - ^4He -D plasmas have shown localized electron heating at the calculated radial position of the mode conversion surface. Up to 80% of the power is measured to be deposited on electrons at the mode conversion surface, in good agreement with numerical modelling. Central electron temperatures greater than 10 keV have been produced with 4 MW of RF power, the highest electron temperature achieved in TFTR in a discharge heated by RF alone. (In comparison, the highest electron temperature achieved in the hydrogen minority heating regime was 7.5 keV with over 10 MW of RF power.) Experiments to investigate mode conversion current drive (MCCD) and fast wave current drive (FWCD) as a means of current profile control have begun. Initial results from the FWCD experiments indicate that 70 kA of current has been driven with 2 MW of RF power in a plasma with a central density of $3.3 \times 10^{19} \text{ m}^{-3}$ and a central electron temperature of 5 keV. With mode conversion current drive, up to 120 kA of current has been driven on-axis in D- ^4He - ^3He plasmas with a central density of $4 \times 10^{19} \text{ m}^{-3}$ and a central electron temperature of 5 keV, for a normalized current drive efficiency of $0.07 \times 10^{20} \text{ A} \cdot \text{m}^{-2} \cdot \text{W}^{-1}$. Off-axis currents of 100 kA have also been driven at $r/a \sim 0.2$. In this latter case, the MCCD has produced changes in the q profile: differences of 50% in the value of q_0 are measured by the motional Stark effect (MSE) diagnostic between plasmas with co- and counter-MCCD [37].

An interaction has also been observed between energetic fusion products and the IBW excited by mode conversion in D- ^3He plasmas. In the initial experiments, the dominant observable wave interaction was believed to be with DD fusion tritons, rather than with DT fusion alpha particles whose population was extremely small in

these plasmas. A strong enhancement of the fusion product losses detected by the probes outside the plasma was observed when the IBW was generated near the plasma axis. The loss mechanism appears to be pitch angle scattering across the passing/trapped boundary. The detectors provide some energy resolution of the escaping particles and show evidence that the fusion products are heated to approximately 1.5 times their birth energy. The effect is further dependent on the phasing of the RF antennas, i.e. the direction of toroidal wave launch. For 180° phasing (symmetric or non-directional launch) the effect is observed at power levels in the 3–4 MW range. For 90° phasing (launch counter to the conventional current) the effect is observed with a threshold of 2–3 MW. For 270° (co-parallel to the conventional current) no RF driven losses have been observed up to the power limit of 4 MW.

In a subsequent experiment, a small tritium gas puff was added to the D- ^3He plasma with IBW heating. When the mode conversion layer was close to the cyclotron resonance layer for alpha particles, there was a further increase in the measured fusion product loss rate, suggesting that the DT alpha particles were also interacting with the waves.

5. SUMMARY

In one and a half years of experiments, TFTR has explored a wide range of physics issues in plasmas with high concentrations of tritium and achieved good progress in fusion power production. Routine operation and maintenance of the facility has been performed in the DT environment. TFTR has been operated at and beyond its original specifications in magnetic field and neutral beam heating power during these experiments. The diagnostics have operated extremely well and a large amount of analysis has already been done to guide future experiments.

In general, DT plasmas show improved characteristics compared to similar deuterium plasmas. The benefits for fusion power production of operating in a regime with $T_i > T_e$ and a highly peaked pressure profile to maximize the reactivity for a fixed β have also been clearly demonstrated in TFTR. Increasing the toroidal magnetic field has produced a significant increase in the achievable fusion power, emphasizing that the peak, rather than the average, achievable plasma pressure is the relevant issue for fusion experiments.

ACKNOWLEDGEMENTS

We wish to thank the entire staff of the TFTR Project for their unstinting efforts in support of these experiments. We thank R.C. Davidson and P. Rutherford for their support and encouragement. This work is supported by US Department of Energy Contract DE-AC02-76-CH03073.
