Abstract

A class of optimization problems in networks of intersecting diffusion domains of a special form of thin paths has been considered. The system of equations describing stationary solutions is equivalent to an electrical circuit built of intersecting conductors. The solution of an optimization problem has been obtained and extended to the analogous electrical circuit. The interest in this network arises from, among other applications, an application to wave–particle diffusion through resonant interactions in plasma.

1. Introduction

Diffusion, or random-walk processes are, in principle, straightforwardly treated in any geometry. Although the treatment is straightforward in practice, it may be difficult to extract general properties of solutions in complex domains. However, certain geometries may be amenable to useful simplifications. An example of particular interest is when the diffusion is restricted to narrow one-dimensional paths. Networks of such domains are frequently used to model porous media [1–5] and fiber networks in brain white matter [6]. Also, a discrete model of diffusion path network, in which particles exhibit random-walk steps between nodes of some graph [7], is used to study computer and social networks [8–13], as well as city traffic [14].

Consider a rectangular network formed of vertical and horizontal intersecting diffusion paths (see Fig. 1). The diffusion tensor on each path is assumed diagonal with the transverse diffusion being much weaker than the diffusion along the path. The diffusion tensor in each intersection region is set to be equal to the sum of tensors of intersecting paths.

![Figure 1](image-url)

where \( \hat{D} \) is a piecewise constant diffusion tensor, yielding a unique stationary solution of Eq. (1), assuming proper boundary conditions [15].

As will be shown in Appendices A and B, the stationary solution of Eq. (1) in a rectangular network of thin diffusion paths can be reduced to a set of linear equations, which can be solved for any particular configuration. However, the dependence of particle fluxes on diffusion coefficients is not linear; any change of the diffusion coefficient of a single path results in a redistribution of
the flux in the whole network. The goal of the present study is to solve an optimization problem of flux rearrangement in a network of diffusion paths. Specifically, we find the diffusion coefficients minimizing a weighted sum of the outgoing fluxes.

The solution of the optimization problem is shown to be a limit of a system with the diffusion coefficients equal to $1, \beta, \ldots, \beta^k$, with $k < 5$ as $\beta$ goes to infinity. As demonstrated in Ref. [3], the network of diffusion paths is equivalent to the network of intersecting one-dimensional conductors (wires). As a result, all theorems true for one of the systems can be immediately applied to the other. The equivalence of systems is demonstrated and the optimization problem in networks of diffusion paths is extended to specific electrical circuits.

Besides being interesting by itself, the optimization problem has an important application to $\alpha$-channeling [16] in tokamaks [17–19] and mirror machines [20,21]. In inhomogeneous magnetic field and an electrostatic wave, a charged particle exhibits random-walk motion along an effectively one-dimensional curve in the velocity space (Appendix C). In a system with several waves, the corresponding paths might intersect, forming a network which is capable of transporting particles between certain areas of the velocity space. In application to cooling down $\alpha$ particles in fusion devices, this concept is known as $\alpha$-channeling. Maximization of the energy extracted from $\alpha$ particles by variation of the wave amplitudes and hence the effective diffusion coefficients of the corresponding paths results in the optimization problem solved in this Letter.

The Letter is organized as follows. In Section 2, we reduce the original system of finite-size intersecting diffusion paths to an approximate system of one-dimensional equations and discuss the relation of the random-walk in networks of paths to the random-walk on oriented graphs. In Section 3, we show the equivalence between the network of diffusion paths and the network of intersecting conductors. The main result of the Letter, a solution of the general optimization problem, is given in Section 4. Section 5 summarizes our conclusions. In Appendix A, we prove that a network of thin diffusion domains can be reduced to a system of intersecting one-dimensional paths. A local optimization of the weighted sum of outgoing fluxes by varying diffusion coefficients is considered in Appendix B. In Appendix C, we show the physical context of the optimization problem. In particular, we discuss the $\alpha$-channeling concept and its optimization in tokamaks and mirror machines.

2. Basic equations

The optimization of a flux distribution in a rectangular network of diffusion paths can be performed analytically if each path can be approximated as a one-dimensional curve. As discussed in Appendix A, if the transverse diffusion is negligible, the path characteristic widths are much smaller than all distances between the paths, and the input flows are quasi-homogeneous, then Eq. (1) yields a stationary solution with a spatial scale much larger than the characteristic path width. Hence, particle flux distribution in a network of thin diffusion paths can be estimated by calculating fluxes in a network of one-dimensional paths (see Fig. 2). Particle density fluxes and particle densities in such network satisfy conditions: (a) particle conservation, reading

$$\bar{j}^x_{j-1} + \bar{j}^y_{j-1} - \bar{j}^x_j - \bar{j}^y_j = 0$$

(2)

and (b) relation between the linear fall of particle density along the path, supporting the constant particle flux between two adjacent intersection volumes, and the flux itself:

$$\bar{j}^x_j = \frac{\bar{j}^x_{j+1} - \bar{j}^x_j}{\Delta x_j}, \quad \bar{j}^y_j = \frac{\bar{j}^y_{j+1} - \bar{j}^y_j}{\Delta y_j}.$$  

(3)

where $\bar{f}_{i,j}$ is the particle density at the intersection of the horizontal and vertical diffusion paths with indices $i$ and $j$ correspondingly, further called the volume $(i,j)$, $\Delta x_j$ and $\Delta y_j$ are the distances between horizontal and vertical paths with indices $i$ and $j + 1$ respectively, and $\bar{j}^x_{i,j}$, $\bar{j}^y_{i,j}$ are density fluxes through the segments linking volume $(i,j)$ with volumes $(i,j + 1)$ and $(i + 1,j)$ correspondingly. The outgoing fluxes are denoted by $\bar{j}^x_{i,0,j}$ and $\bar{j}^y_{0,j}$. The optimization problem of particular physical interest for such a network is to find $\bar{D}_x$ and $\bar{D}_y$ minimizing a linear combination of the outgoing fluxes:

$$\min_{\bar{D}_x, \bar{D}_y} \left( \sum_{i,j} w_{xi} \bar{j}^x_{i,j} + \sum_{i,j} w_{yj} \bar{j}^y_{i,j} \right).$$

(4)

where $\bar{m}$ and $\bar{n}$ are total numbers of horizontal and vertical paths correspondingly, weights $w_{xi}$ and $w_{yj}$ are constants, densities $\bar{f}_{i,j}$, and to the right $\bar{j}^x_{n,j}$ and to the right $\bar{j}^y_{k,j}$ are given.

Random-walk of particles in a network of diffusion paths can be represented as a random-walk on an oriented graph with nodes corresponding to the intersection volumes, sinks and sources and with edges corresponding to possible particle transitions between these nodes. A probability $p_{ij}$ of a particle jump from the node $i$ to the node $j$ is defined by assigning weights to all graph edges according to $p_{ij} = \xi_{ij}/\sum_k \xi_{ik}$, where $\xi_{ij}$ is a weight of the edge connecting the node $i$ with the node $j$, or zero if there is no such edge. One can show that for every diffusion path network, there exists a weight distribution such, that the probabilities of particle jumps between the nodes are the same in both systems. Due to the fact that the inverse is not true, and some optimization problems of the form (4) for the graphs with variation over the edge weights cannot be reformulated for the diffusion path networks, one can argue that the class of optimization problems on oriented graphs is wider. For instance, the problem of maximum extractable energy from plasmas under wave-induced diffusion [22] can be reduced to an optimization of a random-walk on a certain graph. Another example is an optimization of outgoing fluxes in a graph corresponding to the network of diffusion paths, in which jumps between two nodes are permitted in only one direction. Restricting all jumps to be directed towards the sinks, and the weights of the edges located on the same path to be equal, one defines a well posed optimization problem. The solution of this problem can be found using dynamic programming [23] by successively adding horizontal and vertical paths to the system. It can be shown that the optimum is achieved for a system with path weights proportional to $1, \beta, \ldots, \beta^k$ with $k < 5$ as $\beta$ goes to infinity. The same property holds for the system of dif-
fusion paths, however the proof of this fact is different and will be given in Section 4.

3. Equivalence to electrical circuit

Replacing \( j \) by currents, \( f \) by potentials, and \( D \) by conductivities of a unit length \( \rho^{-1} \) in Eqs. (2) and (3), the optimization problem (4) becomes equivalent to an analogous optimization problem for electrical circuit comprised of intersecting homogeneous wires with grounded left and bottom ends \((f = 0)\) and given currents through top and right ends. Equivalence between two systems allows to apply any knowledge about one system to another. For example, the distribution of currents in the circuit can be found as a solution of a variational problem:

\[
\min_j \sum_{k=1}^n j_k^2 \Delta k \rho_k,
\]

where \( n \) is a number of the edges, \( \bar{I} \) is an \( n \)-dimensional vector of the currents, \( \rho_k^{-1} \) is the conductivity of a unit length of the \( k \)th edge, \( \Delta k \) is the length of this edge, and \( S \subset \mathbb{R}^n \) is such that \( \sum_{i \in \mathcal{E}(\nu)} I_i = 0 \) for every circuit node \( \nu \), with \( \mathcal{E}(\nu) \) being a set of indices of edges adjacent to it. Thus reformulated, the variational problem in the network of intersecting diffusion paths reads:

\[
\min_j \sum_{k=1}^n j_k^2 \Delta k / D_k,
\]

where a vector of currents \( \bar{I} \) is replaced by a vector of particle fluxes \( \bar{j} \), and conductivities \( \rho_k^{-1} \) are replaced by diffusion coefficients \( D_k \).

An example illustrating the transition from the optimization problem (4) to that for an electrical circuit is the optimization problem for the intersection of two pairs of parallel wires (Fig. 3(a)). Redirection of all input currents to the corresponding exit even if \( \rho_{x1} \) (\( \rho_{y2} \)) is much smaller than the other weights. However, as shown in Section 4, the minimum of the weighted sum is reached when the resistance \( \rho_{x2} \) (\( \rho_{y2} \)) is the smallest and the system is reduced to the circuit shown on Fig. 3(b). The optimization problem is then reformulated as:

\[
\min_j w = \min_j [w x_1 j_1 + w x_2 j_2 + w y_1 j_3 + w y_2 j_4 + w y_2 j_5],
\]

where output currents are connected by \( j_1 = j_1 + j_2 + j_3 + j_4 + j_5, j_2 / j_5 = \Delta x_1 / \Delta x_2, j_1 / j_4 = \Delta x_1 / \Delta y_1. \) Substituting these expressions into Eq. (5), the problem reduces to the minimization of a linear function

\[
w = w x_1 j_4 \Delta x_1 / \Delta x_1 + w x_2 j_5 \Delta x_1 / \Delta x_2 + w y_2 j_4 + w y_2 j_5 + w x_1 (j_1 - j_4 \Delta x_1 / \Delta x_1 - j_5 \Delta x_1 / \Delta x_2 - j_4 - j_5)
\]

over a triangle in \((j_4, j_5)\) space, formed by three inequalities: \( j_4 > 0, j_5 > 0, j_1 > j_4(\Delta x_1 / \Delta x_1 + 1) + j_5(\Delta x_1 / \Delta x_2 + 1). \) The minimum of a linear function is reached in one of the triangle's vertices [24], and thus three different solutions are possible:

(a) \( \rho_{y2} = \beta \rho_{x1} = \beta^2 \rho_{x1} = \beta^3 \rho_{x1} \)

(b) \( \rho_{y2} = \beta \rho_{x2} = \beta^2 \rho_{x2} = \beta^3 \rho_{x2} \)

(c) \( \rho_{y2} = \beta \rho_{y1} = \beta^2 \rho_{y1} = \beta^3 \rho_{y1} \)

4. Solution for the diffusion path network

In the general case of \( n \times m \) rectangular network of diffusion paths, the minimum in Eq. (4) is reached in the limit \( \beta \to \infty \) of a network with finite diffusion coefficients equal to \( 1, \beta, \ldots, \beta^k \) with \( k < 5 \). This property, which is the main result of the Letter, is proved in this section in two steps. First, we note that the diffusion path with a minimum-weighted sink \( (we take this weight to be equal to 0 for distinctness) should have a diffusion coefficient much greater than the diffusion coefficients of the paths intersecting it. Then, using independence of the subnetworks obtained by partition of the original network by the minimum-weighted path, solutions in each subsystem is obtained separately.

When the sink of the leftmost (bottom) diffusion path has the smallest weight, the optimization problem has a trivial solution. In this case, all particles can be directed to the minimum-weighted path by making its diffusion coefficient large compared to the diffusion coefficient of the bottom horizontal (leftmost) vertical path, which should in turn be much larger than diffusion coefficients of other paths.
In a more general case, when the minimum-weighted sink is not on the leftmost or the bottom path, the optimum is also achieved when the diffusion coefficient \( D_{\min} \) of the minimum-weighted path is much larger than the coefficients \( D \) of the paths intersecting it. This can be proved using a random-walk process analogy. Compare a configuration in which \( D_{\min} \neq D \) with the same configuration having \( D_{\min} \gg D \). For each particle trajectory which does not cross the minimum-weighted path in the large-\( D_{\min} \) system, there is an identical particle trajectory in the finite-\( D_{\min} \) system with the same realization probability and the same output weight. On the other hand, for each trajectory crossing the minimum-weighted path (and then leaving immediately) in the large-\( D_{\min} \) system, there is a family of trajectories in the finite-\( D_{\min} \) system with the same path before the crossing and the same overall probability, but larger or equal average output weight. Thus, averaging over all trajectories, one concludes that the weight defined by Eq. (4) in the large-\( D_{\min} \) system is smaller or equal to the weight in the finite-\( D_{\min} \) system.

The minimum-weighted path divides the network into two sub-networks. An optimal solution to the right of this path (we choose one of which we prove that there are many optimal solutions) is trivial: all vertical diffusion paths have diffusion coefficients much smaller than the diffusion coefficients of every horizontal path. In this case, all particles entering the system to the right of the minimum-weighted path are captured by it. On the other hand, the part of the network to the left of the minimum-weighted path, which we will call enclosed, can be treated as an isolated part in which points of intersection with the minimum-weighted path are replaced by particle sinks with zero weights (the minimum weight in the system). To specify the network geometry, the number of vertical and horizontal paths in the enclosed system are denoted by \( m \) and \( n \) correspondingly, fluxes entering the system from above are denoted by \( j_k \), distances between horizontal or vertical diffusion paths with indices \( i \) and \( i + 1 \) are denoted by \( \Delta x_i \) and \( \Delta y_i \), and the distances from the leftmost vertical path to the left sinks and from the bottom horizontal path to the bottom sinks are denoted by \( a_i \) and \( b_i \) correspondingly.

To solve the optimization problem in a general case, we first analyze a horizontal path with fixed vertical input and output fluxes. Then we solve an optimization problem in a class of networks, in which the relations between vertical fluxes and corresponding differences of densities of adjacent intersection volumes are omitted. We prove that there are many optimal solutions, one of which can be asymptotically reached in a conventional diffusion path network.

Consider a single horizontal diffusion path with vertical fluxes \( j_k \) entering from the above, vertical outgoing fluxes \( i_k \), and the left outgoing flux \( j_0 \). The equation for \( j_0 \) then reads:

\[
j_0 = \sum_{i=1}^{m} \sum_{j=1}^{n} \Delta_{kj} \Delta x_i \geq 0, \tag{6}
\]

\[
j_0 a_k + (j_0 - \Delta_{k1}) \Delta x_1 \geq 0, \tag{7}
\]

\[
j_0 a_k + \sum_{i=1}^{m} \Delta x_i \left( j_0 - \sum_{j=1}^{n} \Delta_{kj} \right) \geq 0 \tag{8}
\]

for \( 1 \leq k \leq n \), and

\[
\sum_{k=1}^{n} \Delta_{kl} \leq j_l \text{ for } 1 \leq l \leq m. \tag{9}
\]

Under these conditions, the minimum weight of the enclosed system is nonnegative and the expression for the linear weight function \( w \) reads:

\[
w = \sum_{k=1}^{n} w_{yk} \sum_{i=1}^{m} \sum_{j=1}^{n} \Delta_{kj} \Delta x_i + \sum_{k=1}^{m} w_{yk} \left( i_k - \sum_{l=1}^{n} \Delta_{kl} \right). \tag{10}
\]

The solution of a linear optimization problem is reached in the vertex of \( nm \)-dimensional manifold defined by Eqs. (6)–(9). This vertex corresponds to the intersection of \( nm \) hyperplanes (out of \( nm + m \) conditions), limiting it. In terms of conditions (6)–(9), this means that \( 0 \leq s \leq m \) vertical output fluxes are zero and there are at least \( nm - s \) intersection volumes with vanishing \( f \). Due to the fact that the horizontal flux cannot emerge from the intersection volume with zero density, there should be exactly \( s \) volumes with nonzero densities in the system with all input fluxes greater than zero. Furthermore, every vertical path with vertical output flux equal to zero should contain just one such volume; henceforth we call such configurations primitive.

The found optimum cannot necessarily be realized in an ordinary network of intersecting horizontal and vertical diffusion paths. However, we show here that any such optimum can be transformed to another configuration with exactly the same weight, which can be represented as a network of both horizontal and vertical diffusion paths. We use a convenient notation, characterizing each primitive configuration by \( (m + 1) \)-dimensional vector \( (a_1, \ldots, a_m, 0) \), where \( a_k \) is equal to \( l \) if the nonzero density volume is situated on the intersection of the vertical path with index \( k \) and the horizontal diffusion path with index \( l \), and \( a_k \) is equal to zero if there is no such intersection volume on this vertical path. Considering a primitive solution of the minimization problem corresponding to a vector \( (a_1, \ldots, a_m, 0) \), we can construct other primitive configurations with the same weight applying a following lemma.

**Lemma 1.** For every primitive configuration of the form \( (a_1, \ldots, a_l, s, r, \ldots, r, 0, a_q, \ldots, a_m, 0) \) or \( (a_1, \ldots, a_l, s, r, \ldots, r, 0) \), where \( s > 0, r > 0 \) and \( s \neq r \), there exists another primitive configuration corresponding to the vector \( (a_1, \ldots, a_l, s, s, \ldots, s, 0, a_q, \ldots, a_m, 0) \) or \( (a_1, \ldots, a_l, s, s, \ldots, s, 0) \), which has the same weight.

**Proof.** Consider a primitive configuration defined by:

\[
f^0_{ij} = 0, \quad i \neq s,
\]

\[
f^0_{ij} = \frac{D_{ij} f^1_{ij}}{D_{xs}}, \quad l + 2 \leq j \leq q - 2.
\]

This completes the proof.
where \( f_{1}^{i} \) and \( f_{2}^{i} \) are particle densities in the original and constructed solutions correspondingly (Fig. 4). In the considered configuration all horizontal fluxes between nonzero density volumes are left the same as in the original system, except for the volumes on vertical paths with indices \( l + 1 \) and \( l + 2 \). This, in turn, means that all outgoing fluxes for vertical paths with indices ranging from \( l + 3 \) to \( q - 2 \) are left equal to zero. Noting that \( j_{c} = j_{a} - j_{b} \), we also see that \( \sum \Delta_{x}^{i,j+1} = \sum \Delta_{x}^{i,j+1} = j_{r+1}^{i+1} \) and \( \sum \Delta_{x}^{i,j+2} = \sum \Delta_{x}^{i,j+2} = j_{r+2}^{i+2} \), which suggests that outgoing fluxes for vertical paths with indices \( l + 1 \) and \( l + 2 \) are equal to zero, too. This proves that the weight of constructed system is equal to the weight of the original configuration because all outgoing fluxes are the same in both configurations.

By substituting the corresponding values to Eq. (11), the optimization problem is reformulated as a minimization of

\[
\min \sum_{j=1}^{m} \mu_{j} \Delta s_{j} \quad (13)
\]

over a manifold limited by Eqs. (6)–(8) and \( m \) conditions \( \Delta s_{j} \leq j_{r}^{i} \).

The solution of this optimization problem defines which of vertical diffusion paths are to have diffusion coefficients proportional to \( \beta^{4} \) and which are to be proportional to \( \beta^{2} \).

5. Conclusions

The optimization of the exit flux rearrangement in the rectangular network of one-dimensional diffusion paths as defined by Eq. (4) is obtained. The solution is also applicable to the electrical circuit comprised of intersecting conductors.

The solution of the optimization problem was obtained by extending the class of the networks over which the optimization was performed and showing that one of the optimal solutions is asymptotically achieved in the original class as diffusion coefficients of certain diffusion paths become large compared to the others. More specifically, the largest diffusion coefficient, proportional to \( \beta^{4} \), where \( \beta \rightarrow \infty \), should be assigned to the minimum-weighted diffusion path (vertical for distinctness). To the right of this diffusion path all vertical paths are assigned \( D_{y} \sim 1 \). The remaining diffusion coefficients are to be determined solving a simpler optimization problem (13) and finding index \( s \), which minimizes Eq. (12). Solution of Eq. (13) determines which vertical paths in the enclosed system are to have \( D_{y} \sim \beta^{4} \) and which \( D_{y} \sim \beta^{2} \). Horizontal paths with indices \( k \neq s \) are assigned \( D_{x} \sim \beta \) and \( D_{x} \sim \beta^{3} \) is assigned to the horizontal path with index \( s \).

Appendix A. One-dimensional model of the particle distribution function

In this appendix we show that a spatial scale of the particle density distribution in a rectangular network of thin diffusion paths greatly exceeds a characteristic diffusion path width. This fact allows us to employ a one-dimensional model for the distribution function, considering dependence only in the path direction.
Consider first the simplest network formed of two straight effectively one-dimensional diffusion paths intersecting at a right angle (Fig. 5(a)). In steady state Eq. (1) reads
\[
D_{xx}(x, y) \frac{\partial^2 f}{\partial x^2} + D_{yy}(x, y) \frac{\partial^2 f}{\partial y^2} = 0. \tag{A.1}
\]
It is solved for the distribution function \( f \) in the domain comprised of two, horizontal and vertical narrow stripes, with widths \( w_h \) and \( w_v \) correspondingly. At one exit of each path (distances \( r_h \) and \( r_v \) apart from the intersection region) the particles are absorbed and \( f = 0 \), at the other two exits input particle flux densities are given, and since the problem is linear, one of the two can be taken equal to zero.

When the parameter \( \mu \), which is responsible for a weak transverse diffusion, is negligible, an approximate solution outside of intersection region reads:
\[
f(x, y) = h_1(y) + h_2(x) - \mu h_1'(y)x^2/(2D_x) - \mu h_2'(y)x^2/(2D_y) + O(\mu^2) \text{ for horizontal path,}
\]
\[
+ h_1(x) + h_2(y) - \mu h_1'(x)y^2/(2D_x) - \mu h_2'(x)y^2/(2D_y) + O(\mu^2) \text{ for vertical path,}
\]
where \( h_1 \) and \( h_2 \) are arbitrary smooth functions with characteristic spatial scales \( l_i = (h_i'/h_i)^{-1/2} \). Furthermore, when condition \( (\mu/\min D_i)(\max L_i^2/\min L_i^2) \ll 1 \), with \( l_i \) being a path length, is satisfied, the solution outside of the intersection region can be approximated by the leading order terms. Thus, the solution in the original domain might be obtained by solving the diffusion equation in the intersection volume with a new set of boundary conditions (see Fig. 5(b)):}
\[
\frac{\partial f}{\partial y} \bigg|_{y=0} = 0, \quad \frac{\partial f}{\partial x} \bigg|_{x=w_h} = -h(y),
\]
\[
\frac{\partial f}{\partial y} \bigg|_{y=-w_v} \approx \frac{f(x,-w_v)}{r_v}, \quad \frac{\partial f}{\partial x} \bigg|_{x=0} \approx \frac{f(0,y)}{r_h}, \tag{A.2}
\]
where \( h(y) \) is the horizontal input flux density.

Eq. (A.1) with boundary conditions (A.2) can be solved by separating variables:
\[
f \approx \sum_{k=0} \mathcal{C}_k \left[ \left( 1 + \frac{2}{\lambda_{ik} r_h - 1} \right) \exp(\lambda_{ik} x) + \exp(-\lambda_{ik} x) \right] \cos \lambda_{yk} y,
\]
where \( \mathcal{C}_k \) are constant coefficients, \( \lambda_{ik} = \sqrt{\lambda_{kk}/D_x}, \lambda_{yk} = \sqrt{\lambda_{kk}/D_y} \), and \( \lambda_{kk} \) is found from the equation:
\[
\tan^{-1}(w_h/\sqrt{\lambda_{kk}/D_y}) = r_v/\sqrt{\lambda_{kk}/D_x}. \tag{A.3}
\]
Assuming that the width of the horizontal path \( w_h \) is much smaller than the distance from the intersection volume to the particle sink \( r_v \), Eq. (A.3) can be solved approximately:
\[
\lambda_{kk} \approx \frac{1}{w_h r_v}, \quad \lambda_{yk} \approx \frac{1}{w_h r_v}, \quad \text{for } k > 0.
\]

The relation \( \lambda_{kk} \ll \lambda_{yk} \) for \( k > 0 \) suggests that if the input flux density \( h(y) \) is quasi-homogeneous, \( \mathcal{C}_k \ll \mathcal{C}_0 \). Neglecting the terms of order \( w_v/r_v \), the fraction of the input particle flux absorbed at the left loss boundary is then given by:
\[
\frac{J_{x=0}}{J_{x=w_v}} = \frac{1 + D_{x w_v r_h}}{1 + D_{x w_v r_h}} \approx \frac{1 + D_{x w_v r_h}}{1 + D_{x w_v r_h}}.
\]

Thus, in a steady state regime, the net particle flux \( J \) incoming by the horizontal diffusion path divides into two outgoing fluxes \( J_h \) and \( J_v \):
\[
J_h \approx J \cdot \frac{1 + D_{x w_v r_h}}{1 + D_{x w_v r_h}}, \quad J_v = J - J_h. \tag{A.4}
\]

Particularly, when \( D_{x w_v r_h} \) is much smaller or much larger than \( D_{x w_v r_h} \), the major part of the input flux will be absorbed at the, whereas in a symmetric system with \( D_{x w_v r_h} = D_{x w_v r_h} \), the input flux is divided into two equal fluxes.

Consider a network comprised of \( n \) horizontal and \( n \) vertical paths, and denote by \( D_{ii} \) and \( D_{ij} \) vectors of diffusion coefficients of horizontal and vertical diffusion paths correspondingly. The flux distribution in such a network is a sum of distributions in two simpler systems: (i) the system with zero vertical input fluxes and the horizontal input flux densities equal to \( j_k(y) \) and (ii) the system with zero horizontal input fluxes and the vertical input flux densities equal to \( j_j(x) \). The solution \( f_{ijk} \) in the intersection region formed by horizontal and vertical diffusion paths with indices \( i \) and \( j \) can be found in the form \( f_{ijk} = X_{ijk}(x)Y_{ijk}(y) \), where \( X_{ijk} \) and \( Y_{ijk} \) satisfy
\[
X_{ijk}' = \frac{\lambda_{ijk}}{D_{xx}}, \quad Y_{ijk}' = -\lambda_{ijk} Y_{ijk},
\]
with \( k \) enumerating eigenfunctions and eigenvalues \( \lambda_{ijk} \). For convenience, we assign the origin to the volume’s left bottom corner.

Considering, for example, a system with zero vertical input fluxes, the vertical eigenfunctions \( Y_{ijk}(y) \) can be found independently in each column as follows. Noticing that the intersection volumes on a vertical path are restricted to have the same horizontal structure, one concludes that \( \lambda_{ijk} \) for different values of \( i \) are connected through \( \lambda_{ijk} = \lambda_{ijk} D_{yy} \). Values of \( \lambda_{ijk} \) can then be found using vertical boundary conditions simplified when \( \mu \) is negligible: (a) boundary condition at the bottom intersection region:
\[
Y_{ijk}'(0) = Y_{i+1,j,k}(0),
\]
where \( b_i \) is the distance to the particle sink on the vertical path with index \( j \); (b) zero input flux density condition at the top intersection region \( Y_{ijk}'(y_h) = 0 \), and (c) conditions necessary to connect adjacent intersection volumes:
\[
Y_{i,j,k}'(y) - Y_{i,j,k}'(y) \Delta y = Y_{i+1,j,k}'(0) \Delta y_i.
\]
where \( y_i \) is the width of the horizontal path with index \( i \), and \( \Delta y_i \) is the distance between horizontal paths with indices \( i \) and \( i + 1 \). These equations can be solved approximately when the vertical and the horizontal diffusion path widths \( x_i \) and \( y_j \) are much smaller than all distances between paths \( \Delta y_i \), \( \Delta y_j \) and distances to the sinks \( a_i \) and \( b_j \), by considering the leading zeroth-order terms in the expansion by small parameters \( \varepsilon_i = \max (|x_i/\Delta y_i|, a_i/y_i, y_j/\Delta y_j, b_j) \). Assuming \( \lambda_j y_j^2 D_{ai}/D_{yj} \ll 1 \) and \( \lambda_j > 0 \) (which we later show to be consistent with our final result), we can use small-value expansions, as we did solving Eq. (A.3), to obtain a simplified equation for the zeroth eigenvalue \( \lambda_{0j} \):

\[
s_{i+1} = \frac{s_i - \frac{D_{x,i+1}}{D_{x,i}} y_{i+1}}{s_i - \frac{D_{x,i+1}}{D_{x,i}} y_{i+1}} y_j + \frac{\Delta y_i}{B_j} r_{i+1},
\]

\[
s_0 = 1,
\]

\[
s_{i+1} = \frac{s_i - \frac{D_{x,i+1}}{D_{x,i}} y_{i+1}}{s_i - \frac{D_{x,i+1}}{D_{x,i}} y_{i+1}} y_j + \frac{\Delta y_i}{B_j} r_{i+1},
\]

(A.5)

where \( r_i = \lambda_{0j} D_{x,i} y_j b_j / D_{y,j} \). For any \( k \), the solution for \( r_k \) of this recursive scheme is of order of one when all equation parameters are of order of one, which suggests that all possible solutions for \( \lambda_{0j} \) are of order of \((yb)^{-1}\) and assumption used above holds. It can be proved that, in the general case, Eq. (A.5) has exactly \( n \) non-negative and no negative solutions, which justifies the assumption \( \lambda_j > 0 \).

Once the eigenvalues \( \lambda_{0j} \) and corresponding eigenfunctions are calculated, the horizontal quasi-homogeneous input flux density can be decomposed by eigenfunctions of the rightmost vertical path. Homogeneity of the input flux density suggests that its decomposition is dominated by the zeroth eigenfunctions corresponding to eigenvalues \( \lambda_{0j} \), because all other eigenfunctions oscillate a few times on a width of at least one of diffusion paths. Noticing that the decomposition of zeroth eigenfunction of one vertical diffusion path by eigenfunctions of the adjacent path contains just zeroth eigenfunctions to the zeroth order term in a small parameter \( \varepsilon = \max \varepsilon_i \), one can couple zeroth-order eigenfunctions of adjacent vertical diffusion paths and find an approximate solution everywhere in the system. Obtained solution is a linear combination of just zeroth eigenvalues (to the zeroth order in small parameters), which suggests that the spatial scale of the particle distribution function is much larger than the characteristic path width.

**Appendix B. Derivative calculation**

In practical applications, the optimal solution obtained in Section 4 might be impossible to achieve. In \( \alpha \)-channeling implementation, for instance, infinitely large diffusion coefficient would imply an infinitely large wave amplitude. One can resolve this by introducing additional limitations on the parameter space or adding terms depending on \( \hat{D}_x \) and \( \hat{D}_y \) into the optimized functional. Numerical algorithms suitable for solution of such extended optimization problem, like gradient descent method, might require calculation of derivatives of the weight function \( w \) with respect to the diffusion coefficients. In this section we outline such calculation for an isolated system enclosed by the minimum-weighted diffusion path.

Denote by \( \hat{x}_i \) a vector of particle densities and their derivatives down the path for the intersection volumes situated on a horizontal path with index \( i \) : \( \hat{x}_i = (\hat{x}_{i1}, \hat{x}_{i2}, \cdots, \hat{x}_{im}, \hat{x}_{i1}', \cdots, \hat{x}_{im}') \), where \( \hat{x}_{ij}' \) is a \( y \)-derivative of \( f \) down the vertical path with index \( j \). To solve for particle densities given incoming fluxes, two \( 2m \times 2m \) linear operators \( \hat{I}_i \) and \( \hat{T}_k \) are introduced:

\[
\hat{x}_{i+1} = \hat{I}_i (D_{ai}) \hat{x}_i,
\]

\[
\hat{T}_k = \hat{T}_{k-1} \cdots \hat{T}_1 = \begin{pmatrix} \hat{A}_k & \hat{B}_k \\ \hat{C}_k & \hat{D}_k \end{pmatrix}, \quad \hat{T}_0 = \hat{I},
\]

\[
\hat{x}_{i+1} = \hat{I}_i (D_{ai}) \hat{x}_i,
\]

\[
\hat{T}_k = \hat{T}_{k-1} \cdots \hat{T}_1 = \begin{pmatrix} \hat{A}_k & \hat{B}_k \\ \hat{C}_k & \hat{D}_k \end{pmatrix}, \quad \hat{T}_0 = \hat{I},
\]

where \( \hat{I} \) is an identity operator. Given the \( m \)-dimensional vector of input fluxes \( \hat{I}_0 \) entering the system from above, the state vector at the bottom diffusion path is calculated:

\[
\hat{x}_1 = \hat{I}_1^{-1} (D_{ai}) \begin{pmatrix} \hat{A}_y^{-1} \hat{I}_0 \\ \hat{B}_y^{-1} \hat{I}_0 \end{pmatrix} = \begin{pmatrix} \hat{C}_n + \hat{D}_n \hat{A}_n^{-1} & 0 \\ 0 & \hat{C}_n + \hat{D}_n \hat{A}_n^{-1} \end{pmatrix}^{-1} \begin{pmatrix} \hat{A}_y^{-1} \hat{I}_0 \\ \hat{B}_y^{-1} \hat{I}_0 \end{pmatrix},
\]

where \( (\hat{A}_k)_ij = \delta_{ij} b_j \) and \( (\hat{A}_y)_ij = \delta_{ij} D_{yj} \) are \( m \times m \) matrices and \( \hat{T}_n \) is constructed by introducing a virtual horizontal path with index \( n + 1 \) having vanishing \( D_{x,n+1} \) and situated arbitrary distance \( \Delta y_n \) apart from the adjacent path. The value of the weight function can then be calculated:

\[
\hat{w} = \begin{pmatrix} \hat{w}_y (\hat{A}_y, \hat{B}_y) 0 \\ 0 \end{pmatrix} + \begin{pmatrix} \hat{w}_x D_{ai} \hat{I}_1 + \hat{w}_x D_{a2} \hat{I}_2 + \cdots \\ \hat{w}_m D_{am} \hat{I}_{n-1} \end{pmatrix} \hat{x}_1,
\]

(B.1)

where \( (\hat{S}^{-1})^{-1} = -\hat{S}^{-1} \hat{S}^{-1} \), and

one can differentiate Eq. (B.1) with respect to \( D_{sk} \) to obtain:

\[
\frac{\partial \hat{w}}{\partial D_{sk}} = \begin{pmatrix} \hat{w}_x \hat{I}_1 + \hat{A}(\hat{I}_k - \hat{T}_k (D_{sk} = 0)) \hat{I}_k \hat{x}_1 \\ -I_y \hat{A}_y \hat{B}_y \hat{I}_0 + (\hat{B})_i (\hat{I}_k - \hat{T}_k (D_{sk} = 0)) \hat{x}_1 \end{pmatrix},
\]

(B.2)

where

\[
\hat{A} = \begin{pmatrix} \hat{w}_x D_{ak+1} D_{sk+1} \hat{I}_0 + \hat{w}_x D_{ak+2} D_{sk+2} \hat{I}_k \hat{x}_1 \\ \hat{a}_{sk+2} D_{sk+2} \hat{I}_k \hat{x}_1 + \cdots \\ \hat{a}_{sk+k} D_{sk+k} \hat{I}_k \hat{x}_1 + \cdots \end{pmatrix},
\]

\[
\hat{B} = \begin{pmatrix} \hat{w}_x D_{ai} \hat{I}_1 + \hat{w}_x D_{a2} \hat{I}_2 + \cdots \\ \hat{w}_m D_{am} \hat{I}_{n-1} \end{pmatrix},
\]

and where we used \( D_{sk} \hat{S}^{-1} = \hat{S} (D_{sk} = 0) \). Consider a network from the original by removing kth horizontal path, or equivalently by taking \( D_{sk} = 0 \); henceforth we call such network reduced. Denote by \( \hat{T}_e \), such vector of input fluxes entering the reduced system, that the values of \( f \) at its bottom horizontal path are equal to \( \hat{x}_1 \):

\[
\begin{pmatrix} \hat{A}_y^{-1} \hat{I}_1 \\ \hat{B}_y^{-1} \hat{I}_0 \end{pmatrix} = \hat{S} (D_{sk} = 0) \hat{x}_1,
\]

the last term in the right-hand side of Eq. (B.2), multiplied by \( D_{sk} \), can be interpreted as the difference of weights of the original system with \( s = s_0 \) and the same system with \( s = s_1 \). The first term in the right-hand side of Eq. (B.2), multiplied by \( D_{sk} \), is equal to the sum of weights of horizontal paths with indices \( k, k + 1, \ldots, n \) in the original system minus the sum of weights of paths with indices \( k + 1, \ldots, n \) in the reduced system with \( s = s_1 \). Noticing that all outgoing vertical fluxes and horizontal fluxes leaving through sinks with indices \( 1, \ldots, k - 1 \) of the reduced system with \( s = s_1 \)
are equal to the same fluxes of the original system with \( \overline{I} = I_0 \) (because \( \overline{I}_1 \) is the same in both systems), Eq. (B.2) finally takes the form:

\[
D_{sk} \frac{\partial w}{\partial s_k} = \left[ \vec{w}_{\vec{y}} \right] \cdot \tilde{\vec{k}} (D_{sk} = 0) \vec{x}_1
- \left( \vec{w}_{\vec{y}} \right) \cdot \tilde{\vec{k}} (D_{sk} = 0) \vec{x}_1.
\]

According to this relation, the derivative of the system weight with respect to \( D_{sk} \) is simply equal to the difference of weights of the original system with \( I = \overline{I}_r \) and the reduced system with \( I = I_r \).

**Appendix C. Physical background**

In the presence of exact or approximate integrals of motion, particle trajectories are constrained to lie in a lower-dimensional manifold of the phase space, thus restricting particle diffusion in stochastic systems. A particle resonantly interacting with an electrostatic wave in a magnetic field is an example of the system with constrained diffusion. The equation of particle motion reads:

\[
m\ddot{v} = -Reiq\psi k e^{-i\omega t + ik_{\parallel}z + i\vec{k}_1 \vec{r}_1} - \frac{q}{c} \vec{v} \times \vec{B}, \quad (C.1)
\]

where \( m, q, \vec{r} \) and \( \vec{v} \) are the particle mass, charge, position and velocity correspondingly; \( \vec{B} = 2B_1 \) is the magnetic field assumed constant; \( \psi, \omega, \tilde{\vec{k}} \) are the wave amplitude, the frequency and the wave-vector correspondingly. Introducing new coordinate \( z = z - \omega t/k_\parallel \), one can make a canonical transformation in the Hamiltonian corresponding to Eq. (C.1), to obtain [25]:

\[
\frac{m\dot{v}_1^2}{2} + m(v_0 - \omega/k_1)^2 + Reiq\psi e^{-i\omega t + ik_{\parallel}z + i\vec{k}_1 \vec{r}_1} = C,
\]

where \( C \) is a constant of motion. When the wave amplitude is small and \( q\psi_0 \ll C \), this integral restricts the particle trajectory in the velocity space to a ring with the center at \( \vec{v}_c = 2\psi_0 \omega/k_1 \), and with a width \( \Delta u \sim q\psi/mC \), where \( z_0 \) is a unit vector directed along the \( z \) axis. If the resonance condition \( \omega = k_1 u_1 = n\Omega = neB/mc \) is satisfied, a typical change of the particle velocity due to interaction with the wave greatly exceeds the ring width \( \Delta u \) and the particle trajectory in the velocity space is directed along the arcs forming the ring.

In physical systems where the wave-particle interaction is not a continuous process, but is broken into many short acts, in which particle phases are not correlated (an example being a mirror machine with localized rf regions), the particle dynamics is stochastic. In this case, the volume of the phase space subjected to the strongest diffusion contains resonant particles moving along the circle \( v_1^2 + (v_1 - \omega/k_1)^2 = \text{const} \). Due to resemblance of this volume to a thin neighborhood of one-dimensional curve, it is frequently referred to as a diffusion path. A single wave at finite amplitude can also induce this diffusion [26].

The \( \alpha \)-channeling concept is based on arranging diffusion paths in the velocity space, in such a way that they connect areas of phase space where hot \( \alpha \) particles are born to the much lower-energy areas where they are lost [16]. As a result of population inversion created along these paths, an average flux of \( \alpha \) particles is induced, and the particles leave the system and cool at the same time, quickly converting their initial energy to the wave. In mirror machines, for instance, \( \alpha \)-channeling can be implemented by arranging several rf regions along the device axis [20,21]. Varying parameters of the wave regions, the configuration of diffusion paths in the phase space can be optimized to extract maximum energy from \( \alpha \) particles. In optimal configurations, it might be advantageous or even unavoidable for several diffusion paths to intersect, and, because the paths intersect with the loss boundary at different values of energy, the optimization problem of selecting wave amplitudes (and thus effective diffusion coefficients at the paths) minimizing the output energy of all leaving particles is posed. Similar optimization problems occur when \( \alpha \)-channeling is applied to tokamaks [17–19].
